## Summary

The Norwegian Geotechnical Institute (NGI) has carried out P-wave measurements on drill cores from borehole KAV04A at Simpevarp in June 2004. Thirty three P-wave velocity measurements have been carried out from a total of 901 m of core.

The results from the P-wave velocity measurements over the whole length of the borehole show maximum velocities between 5,022–5,980 m/s and a variable anisotropy ratio of between 1.00 to 1.08. The maximum velocity appears to be constant with depth and lies between 5,432–5,980 m/s, with an outlying low value of 5,022 m/s at 796 m.

The foliation is not identifiable over most of the core and the orientation of the principal velocities could not be identified relative to the foliation.

# Sammanfattning

Norges Geotekniska Institut (NGI) har under juni 2004 utfört P-vågsmätningar på borrhärlar från borrhål KAV04A i Simpevarp. Sammanlagt utfördes 33 st hastighetsbestämningar av P-vågen på kärnprover som utvalts från borrhärlar med en sammanlagd längd av 901 m.

Resultaten längs hela borrhärlan uppvisar en maximihastighet på mellan ca 5 020–5 980 m/s och en varierande anisotropikvot mellan 1.00 och 1.08. Den maximala hastigheten är relativt konstant och ligger mellan 5 440–5 980 m/s med ett undantag där hastigheten är 5 020 m/s vid borrhärlarlängden 796 m. Någon tydlig identifierbar foliation längs kärnan har inte kunnat identifieras och därmed har inte hastigheterna orientering till foliation kunnat bestämmas.

# 1 Introduction

The Norwegian Geotechnical Institute (NGI) has carried out P-wave velocity measurements on cores from borehole KAV04A at Simpevarp in Sweden in accordance with SKB Aktivitetsplan AP PS 400-04-054 (SKB internal controlling document).

The work was carried out by Panayiotis Chryssanthakis and Paweł Jankowski during the period 14<sup>th</sup>–15<sup>th</sup> June 2004 in accordance with SKB's method description MD 190.002 version 1.0 (SKB internal controlling document).

## 2 Objective and scope

The purpose of the testing is to determine the P-wave velocity transverse to the core axis. The P-wave velocity is a parameter used in the rock mechanical model which will be established for the candidate area selected for site investigations at Simpevarp.

The number of core specimens tested and the number of tests performed are given in Table 2-1.

The results from the P-wave velocity measurements are presented in this report by means of tables, figures and spreadsheets.

**Table 2-1. Total number of P-wave velocity specimens and measurements.**

### 3 Equipment

The measurements were conducted using Panametrics Videoscan transducers with a natural frequency of 0.5 MHz. These were mounted in a special frame to hold them in contact with the core (see Figure 3-1). Special wave guides, metal shoes with a concave radius similar to the core, were installed between the transducers and the core. The equipment was designed and constructed specially for this contract by NGI, based on the information presented in SKB report entitled "Detection of Anisotropy by Diametral Measurements of Longitudinal Wave Velocities on Rock Cores" /Eitzenberger, 2002/.

A strong sine-wave pulse at the natural frequency of the transducers was used as the acoustic signal source. The arrival of the signals was measured using a PC with a high speed data acquisition board and software to emulate an oscilloscope (see Figures 3-2 and 3-3). The time pick for the first break was taken as the beginning of the first transition, i.e. the point where the received signal first diverges from the zero volts line. In order to provide consistent interpretation of the time pick, one operator (PC) made all the interpretations. The time pick was measured with a precision better than 0.01 $\mu$ s. The instrumentation was calibrated using a cylinder of aluminium of known acoustic velocity of the same diameter as the core. Several measurements were taken each day on the calibration piece to check operation of the system.

A thin layer of a thick honey was used, as a coupling medium as this proved to be one of the most effective of different media tested and was easily removed by washing without damaging or contaminating the cores.

**Figure 3-1.** Detail of NGI's apparatus for measuring acoustic P-wave travel time transverse borehole core. The aluminium cylinder for calibration of the device is on the left.

## 4 Execution

### 4.1 Sampling

Thirty core specimens of length ca. 200–500 mm and diameter about 50 mm were selected from borehole KAV04A while the complete length of the borehole (depth 100 m–1,001.20 m) was displayed on the racks in the core shed at Simpevarp. The specimens were selected together by NGI and SKB.

These specimens represent the Ävrö granite found over most of the length of the borehole. Geological logging of core has been carried out by SKB. No detailed geological description has been attempted by NGI.

The depths used to describe the location are those marked on the core and core boxes at the time. Detailed description of the specimens is available from the detailed core log by SKB. At the time of sampling, the core had been exposed to the atmosphere at room temperature for an extended period and may be presumed to be air-dried, though no measurements of the moisture content were made.

### 4.2 Test method

Tests were made at 30° intervals around the core, starting at 0° parallel with the foliation. However, where the foliation was not identifiable the first test was made at a random orientation. The cores were all oriented such that successive measurements were made clockwise looking down the borehole (see Figure 4-1). The cores were marked by attaching a piece of self-adhesive tape that had been previously cut to the appropriate lengths and marked up with the locations for the tests. These marks were then transferred to the core with a permanent marker. The cores may thus be checked at any time to ascertain the location and orientation of the tests.

Each test sample comprised a minimum of two consecutive determinations of acoustic pulse travel time at each of six locations around the core (at 0°, 30°, 60°, 90°, 120° and 150°) at one cross section. The seating of the transducers and application of the coupling medium was adjusted in cases where there was a significant difference between the time picks, and additional measurements were made until two similar time picks were obtained. The average of the two measured time picks was recorded.

**Figure 4-1.** Orientation of measurements.

As the travel time includes a number of other factors, such as travel through the wave guides, time pick method, and delay due to the oscilloscope triggering on the rising part of the sine-wave, the determination of the true travel time was calibrated using an aluminium cylinder with known P-wave velocity. The correction factor determined in the calibration tests was subtracted from all the measurements on the rock cores.

The diameter of the core was measured using a calliper with an accuracy of 0.01 mm and the P-wave velocity determined by dividing the diameter (in mm) by the travel time (in  $\mu\text{s}$ ) and multiplying by 1,000 to obtain the velocity in m/s.

### **Analysis**

Since the acoustic velocity is dependent on the elastic properties of the material, the results were analysed similarly to determining the stress or strain tensor in the material. In this case the velocity in the orientation  $\theta$  is given by:

$$V_{\theta} = V_x \cos^2 \theta + V_y \sin^2 \theta + 2 \cdot V_{xy} \sin \theta \cos \theta \quad (1)$$

A simple regression analysis of the six measurements was used to determine the values of  $V_x$ ,  $V_y$ , and  $V_{xy}$  (where the X-axis is parallel with the foliation where identifiable).

These values were used to model the complete velocity profile around the core.

The magnitude and orientation of the principal velocities were determined from the Eigen values and vectors of the 2D tensor matrix:

$$\begin{vmatrix} V_x & V_{xy} \\ V_{xy} & V_y \end{vmatrix} \quad (2)$$

### **4.3 Nonconformities**

Tests were made at 30° intervals around the core instead of 45° intervals, which were suggested in the Method Description. This was the only nonconformity to the controlling documents.

## 5 Results

### 5.1 Summary of results

The results of the determinations of the travel time and velocity for all the tests are presented in Table 5-1, and the velocity and anisotropy are shown diagrammatically versus borehole length in Figures 5-1 and 5-2.

The results of calculated principal velocities, and the anisotropy ratio are presented in Table 5-2, and shown diagrammatically versus borehole length in Figures 5-3 to 5-4. The foliation was not identifiable over most of the core and therefore the orientation of the maximum velocity could not be determined.

The results of calibration determinations for the system are shown in Appendix A. The results are also reported to SICADA (field note no Simpevarp 415).

### 5.2 Discussion

#### *Accuracy and repeatability*

Calibration tests on an aluminium cylinder indicated a variation of  $\pm 0.02 \mu\text{s}$  in determination of the time pick, equivalent to differences in velocity of about  $\pm 12 \text{ m/s}$ . Some of this variation may be explained by temperature variations, thickness of coupling medium and seating of the shoes. Similar variations may be expected from the measurements on the cores.

Tests on cores were repeated at two locations, 331.15 m, 538.40 m and 735.80 m, after the first series of tests were completed. These tests were repeated to investigate and determine typical values for repeatability of velocity determinations.

The repeatability of the diameter measurements was about  $\pm 0.01 \text{ mm}$  which gives an error of about  $\pm 1 \text{ m/s}$ .

At 331.15 m the difference in magnitude of the velocities is 5–90 m/s, the anisotropy ratio is the same and there about  $10^\circ$  difference in orientation. At 538.40 m the difference in magnitude of the velocities is 5–86 m/s, the anisotropy ratio is the same and there about  $15^\circ$  difference in orientation. At 735.80 m the difference in magnitude of the velocities is 43–233 m/s, the anisotropy ratio differs by 0.01 and there about  $35^\circ$  difference in orientation. The large difference in the orientation of the stresses is due to the significant differences between the two sets of measurements in this particular case and the low anisotropy which means that the calculation of the orientation angle is not well constrained.

The differences in the measured velocities on the calibration cylinder and rock cores are presumably due to temperature changes, the problems in seating the transducers and obtaining good signal contact with the material and due to the interpretation of the time pick.

Generally there is a good fit between the measurements and the best fit line (model fit) which suggests that random type errors are relatively small. At 331.15 m the maximum difference was 58 m/s, at 538.40 m the maximum difference was 40 m/s, and at 735.80 m the maximum difference was 39 m/s, see Figure 5.5.

Typically in the entire series of tests, the average deviation between the measured value and the model fit is about 0.44% (about 22 m/s), with a maximum error of 2.5% (about 125 m/s).

The deviation between the model fitted to the data and the measured data reported here is somewhat better or equal to that found in the previous work /Chryssanthakis and Tunbridge, 2003a, b, c, d, e, f/. The results are also consistent, except for the tests at 735.80 m depth where there was a significant discrepancy between the two sets of readings, which may have been due to not setting the wave guides in exactly the same positions. It is, however, concluded that the measurement errors are similar to those determined previously.

It is therefore concluded that:

- the repeatability of the reported results for velocities is generally better than  $\pm 100$  m/s;
- the error in the orientation of the principal velocities is generally better than  $\pm 10^\circ$ ;
- the errors in determining the anisotropy ratio and orientation are partly mitigated by the redundant data and regression analysis and it is considered that the error in the anisotropy ratio is generally better than  $\pm 0.02$ .

## **Conclusions**

The results from the P-wave velocity measurements over the whole length of the borehole show maximum velocities between 5,022–5,980 m/s and a variable anisotropy ratio of between 1.00 to 1.08. The maximum velocity appears to be constant with depth and lies between 5,432–5,980 m/s, with an outlying low value of 5,022 m/s at 796 m.

The foliation is not identifiable over most of the core and the orientation of the principal velocities could not be identified relative to the foliation.
